ABSTRACT

The present paper discusses an integrated electrochemical decolorization/degradation treatment procedure of indigo carmine dye, which comprises electrocoagulation, electrooxidation and advanced electrochemical oxidation using the electro-Fenton process.

The electrocoagulation process is performed by sacrificial iron electrodes, the indirect electrooxidation process by dimensionally stable Ti/Pt and graphite electrodes in NaCl electrolyte solution, and the electro-Fenton process by iron electrodes and added amounts of H₂O₂. All electrochemical experiments are conducted in the same electrochemical cell with the same apparent electrode surface and inter-electrode distance.

The three different electrochemical processes are discussed, their efficiencies compared and evaluated. The initial dye concentration of 100 mg l⁻¹ was fast and efficiently removed in only a few minutes of electroprocessing time. The electro-Fenton treatment is the fastest, most efficient and economical process operated at very low current densities of 0.33 and 0.66 mA cm⁻² and consuming only 4.75x10⁻³ and 5.23x10⁻³ kWh m⁻³ of treated solution respectively. The electrocoagulation treatment with iron electrodes and the electrooxidation process with Ti/Pt electrodes conducted at applied current densities of 5 mA cm⁻² consumed 0.511 and 0.825 kWh m⁻³ of treated solution respectively. The proposed procedure is a safe, economical and efficient method for removal of indigo carmine dye from aqueous solutions and dye house effluents.

Keywords: Dye house effluents, electrochemical coagulation, anodic oxidation, electro-Fenton, wastewater remediation.

1. Introduction

The textile industry consumes enormous amounts of water during dyeing and finishing operations. Typical medium-scale textile factories produce approximately 1000 m³ of wastewater per day. It is estimated that around 30% of the applied dyes remain unfixed and are discharged in the effluent. Dye bearing wastewaters are toxic for the environment since dyes are stable compounds and may cause carcinogenesis. Conventional biological treatment processes are often less successful because most dyes are barely or non biodegradable (Beydili et al., 2001; Aygün et al., 2012).

Indigo Carmine (5.5’-indigo disulfonic acid disodium salt) is a dark blue dye mainly used in the textile industry for the dyeing of polyamide fibers and denim (blue jeans) (Secula et al., 2011). Indigo Carmine is also used as dye in food and cosmetics industry. Several processes have been suggested for removal of Indigo Carmine and other dyes from wastewater including adsorption (Kyzas et al., 2012), photochemical (Caliman et al., 2007) and electrochemical methods (Ammar et al., 2006; Flox et al., 2006; Secula et al., 2011; Dogan & Turkdemir, 2012; Hammami et al., 2012).

Dogan & Türkdemir, 2005, reported an almost 100% removal of color and 60% of COD from an 0.1 w/v aqueous indigo carmine solution in 90 min. residence time by the electrooxidation process with platinum electrodes. Secula et al., 2011, achieved almost 99% removal of indigo carmine from an aqueous solution containing 40 mg l⁻¹ dye by the electrocoagulation process with steel electrodes, at a current density of 10.91 A m⁻² and a residence time of 180 min. Ammar et al. (2006), studied the electrochemical oxidation of indigo carmine at boron-doped diamond anode, whereas Flox et al. (2006), and Hammami et al. (2012), worked on electro-Fenton degradation of the dye and obtained similar results. As far as we are aware, no other paper has appeared in literature up to now presenting a combination and comparative study of all three electrochemical processes i.e. the electrocoagulation, electrooxidation and electro-Fenton processes.

Electrochemical processes for pollution abatement have been proved viable alternatives or complementary to biological treatment in some instances, especially when pollutants are recalcitrant to biological processing. They are based mainly on direct anodic oxidation at dimensionally stable electrodes (Vlyssidies et al., 1999; Chatzisymeon et al., 2006; Motoc et al., 2012), advanced electrochemical oxidation (Otruran and Brillas, 2007; El-Desoky et al., 2010; Wang et al., 2010) and electrocoagulation with sacrificial aluminium or iron electrodes (Kabdasli et al., 2009; Körbahi et al., 2011; Dermentzis et al., 2011a; Dermentzis et al., 2011b). The advantages of electrochemical treatment are various and well documented: the catalyst/electrode is immobilized i.e. without the need to separate the catalyst from the reaction mixture, the variables such as current and potential are easily controlled facilitating automation of the process.

The present paper discusses an integrated electrochemical decolorization/degradation treatment of the Indigo Carmine dye, which comprises electrocoagulation with iron sacrificial electrodes, indirect anodic oxidation at dimensionally stable Ti/Pt and graphite anodes in NaCl electrolyte solution and advanced electrochemical oxidation using the electro-Fenton process with iron sacrificial anode and added amount of hydrogen peroxide. The efficiencies of the three different electrochemical processes are compared and evaluated.

2. Methods

2.1 Chemicals

NaCl, NaOH and H₂O₂ were of analytical grade (Merck). pH was adjusted with 0.1 mol l⁻¹ solutions of H₂SO₄ and NaOH as required. The reactive dye indigo carmine (Disodium (2E)-3-oxo-2-(3-oxo-5-sulfonato-1,3-dihydro-2H-indol-2-ylidene)-5-indoline-sulfonate) was purchased from Aldrich (CAS Nr: 860-22-0). Its structure is shown in Figure 1.
2.2 Apparatus

A laboratory model DC power supply apparatus (STELL TRAFO, PHYWE Systeme GmbH & Co. KG Germany) was used to maintain constant DC current. Voltage and current were measured by a multimeter (PHYWE). Conductivity was measured by means of a conductometer (inoLab Cond. Level 1, WTW). pH was measured by a WTW pH-meter. Electrolyses were conducted at room temperature in a cylindrical glass cell of 500 ml. The treated solution of 250 ml was rigorously stirred with a magnetic bar at 500 rpm. The electrodes for the electrooxidation experiments were two platinized titanium plates (Ti/Pt) and two graphite plate electrodes, while for electrocoagulation and electro-Fenton two iron plates (obtained commercially) were used with an apparent area of 30 cm² each.

2.3 Analytical Procedures

UV-VIS Spectrophotometry (HITACHI U-2000, Japan) was used for spectrographic analysis of dye concentrations. Known concentrations of the indigo carmine dye solution were scanned at optimum absorption wavelength of 612 nm wavelength for generating the calibration plot. Samples were diluted using distilled water if the absorbance exceeded the range of calibration curve. All samples were filtered using polytetrafluorethylene filters with a pore size of 0.45 μm (Whatman).

2.4 Experimental Procedures

All electrochemical experiments: electrocoagulation, electrooxidation and electro-Fenton were conducted in the 500 ml electrochemical reactor. The inter-electrode distance was 0.5 cm. H₂O₂ was added to the reactor during the electro-Fenton treatment. The concentration of NaCl was 6 g l⁻¹. The applied current densities were 5 and 10 mA cm⁻² for electrocoagulation, 5 mA cm⁻² for electro-oxidation, while only 0.33 and 0.66 mA cm⁻² for electro-Fenton was used. pH was adjusted to 6.9 for electrocoagulation and to 3 for electro-Fenton and electrooxidation experiments respectively.

2.5 Brief description of electrochemical processes

2.5.1 Electrocoagulation

Electrocoagulation is a process consisting of creating metallic hydroxide flocks inside the wastewater by electrodissolution of soluble anodes made of iron or aluminum. The main reactions occurring during iron electrocoagulation produce ferrous and ferric ions at the sacrificial anode and hydroxide ions as well hydrogen gas at the cathode:

\[
\text{Fe} \rightarrow \text{Fe}^{2+} + 2e^- \quad \text{(anode)} \tag{1}
\]

\[
\text{Fe} \rightarrow \text{Fe}^{3+} + 3e^- \quad \text{(anode)} \tag{2}
\]

\[
2\text{H}_2\text{O} + 2e^- \rightarrow 2\text{OH}^- + \text{H}_2 \quad \text{(cathode)} \tag{3}
\]

The generated Fe²⁺, Fe³⁺ and OH⁻ ions react to form various monomeric and polymeric species which finally result in situ formation of gelatinous Fe(OH)₂ and Fe(OH)₃ effecting the coagulation and co-precipitation or H₂ flotation of particulates from the solution by adsorption.

2.5.2 Anodic oxidation

Organic matter can be anodically destroyed in two different mechanisms, namely: direct oxidation, where the pollutants are adsorbed on the anode surface and destroyed by the electron transfer reaction and (b) indirect oxidation in the liquid bulk by the electrochemically mediated oxidants, such as chlorine, hypochlorite, hydroxyl radicals, ozone and hydrogen peroxide. In anodic oxidation organic pollutants are attacked by the absorbed hydroxyl radicals formed as intermediates from water oxidation to O₂ at the surface of dimensionally stable anodes (graphite, Pt, TiO₂, IrO₂, PbO₂ or boron doped diamond electrodes).
2.5.3 Electro-Fenton process

Fenton’s reagent is an acidic mixture of hydrogen peroxide and Fe$^{2+}$, where free hydroxyl radicals with high oxidative power are produced as follows:

$$\text{Fe}^{2+} + \text{H}_2\text{O}_2 \rightarrow \text{Fe}^{3+} + \text{OH}^- + \text{OH}^- \quad (4)$$

Recently, the Fenton’s reagent has been produced in situ electrochemically (electro-Fenton) in two ways:

(a) by addition of a catalytic amount of Fe$^{2+}$ ions, reduction of oxygen and regeneration of Fe$^{2+}$ on a suitable cathode in acidic media:

$$\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2\text{O}_2 \quad \text{E}^0 = 0.67 \text{ V} \quad (5)$$

$$\text{Fe}^{3+} + \text{e}^- \rightarrow \text{Fe}^{2+} \quad \text{E}^0 = 0.771 \text{ V} \quad (6)$$

and

(b) by addition of H$_2$O$_2$ and electrochemical production of Fe$^{2+}$ ions with a sacrificial Fe anode according to the anodic reaction (1)

In this case, a part of Fe$^{3+}$ ions is produced from Fenton’s reaction (Eq.4) between supplied H$_2$O$_2$ and electroregenerated Fe$^{2+}$ which precipitates as Fe(OH)$_3$. Therefore, the organic pollutants can be removed by oxidation with OH$^*$ radicals and simultaneously by electrocoagulation with the Fe(OH)$_3$ precipitate (Brillas and Casado, 2002; Oturan and Brillas, 2007; Yatmaz and Uzman, 2009).

3. Results

3.1 Removal of indigo carmine by electrocoagulation

The decolorization of the indigo carmine wastewater was investigated by electrocoagulation using iron electrodes as anode and cathode at different current densities and NaCl (6 g l$^{-1}$) as electrolyte solution. pH was adjusted to the optimum value of 6.9 (Mollah et al., 2009) with a dilute NaOH solution.

![Figure 2. Effect of applied current density on residual dye concentration versus time during electrocoagulation treatment of indigo carmine](image)

According to Figure 2, for the two current densities 5 and 10 mA cm$^{-2}$ the initial concentration of 100 mg l$^{-1}$ indigo carmine fell under the detection limit (0.008 mg l$^{-1}$) in 35 and 20 minutes of electrolysis.
time respectively. The removal rate is faster with increasing current density. This is a presumable phenomenon, as the current density determines the coagulant dosage rate, the bubble production and the flock size and growth (Koshla et al., 1991). The initial solution pH of 6.9 changed to 8.8, i.e. no significant pH change was observed during electroprocessing. During the electrocoagulation process the indigo carmine dye is not destructed. The dye molecule is absorbed and relocated as a whole in the electro-generated Fe(OH)$_3$ precipitate.

The electrical energy consumptions for the two runs at the corresponding current densities of 5 and 10 mA cm$^{-2}$ are calculated from Eq.7:

$$E = \frac{U \times I \times t}{V} \quad (7)$$

where:

$U =$ voltage (Volts), $I =$ current intensity (A), $t =$ time (s) and $V =$ solution volume of wastewater, and amount to 0.511 and 0.825 kWh m$^{-3}$ of treated dye wastewater respectively.

3.2 Degradation of Indigo carmine dye by electrooxidation

The degradation of indigo carmine from aqueous solution of 100 was investigated by indirect electrooxidation at platinized titanium (Ti/Pt) and graphite electrodes as anode and cathode. NaCl (6 g l$^{-1}$) was used as supporting electrolyte to increase the solution conductivity and therefore reduce the resistance and the electrical energy consumption. H$_2$SO$_4$ was added to the dye solution until it reached pH $= 3$. As has been shown, (Chatzisymeon et al., 2006; Dogan and Turkedemir, 2012; Vlyssides et al., 1999; Yatmaz and Uzman, 2009), acidic electrolyte solutions favor the electrooxidation process by increasing the oxidation power of the oxidants (Cl$_2$, HOCI, O$_3$, OH*, H$_2$O$_2$) which are produced during the electrooxidation treatment of organic pollutants. For this reason the optimum acidic solution of pH $= 3$ was selected as the operation pH. The applied current density was held at 5 mA cm$^{-2}$.

According to Figure 3 the initial dye concentration of 100 mg l$^{-1}$ was completely reduced in 20 and 35 minutes of electroprocessing using Ti/Pt and graphite electrodes respectively. This is due to the anodic oxidation of Cl$^-$ ions and the formation of free chlorine. As known, chlorine in acidic solution is a strong oxidizing agent causing indirect oxidation of the dye in the bulk solution.

![Figure 3](image)

**Figure 3.** Residual dye concentration versus time during electrooxidation of indigo carmine in NaCl electrolyte at Ti/Pt and graphite electrodes.

The electrical energy consumptions calculated from Eq.8 for the electrooxidation treatment with Ti/Pt and graphite electrodes are 0.874 and 1.75 kWh m$^{-3}$ of treated dye wastewater respectively.
3.3 Degradation of indigo carmine by electro-Fenton

Fenton reagent is generally conducted in acidic solutions with pH values ranging from 2 to 4 with pH=3 being the optimum. Hence, the dye solution was acidified with H₂SO₄ until it reached pH=3. The electro-Fenton experiment was conducted at low applied current densities of only 0.33 and 0.66 mA cm⁻² with iron plate electrodes as anode and cathode and initial addition of 2 ml of H₂O₂ 1 mol l⁻¹ solution. The solution pH tending to increase slightly during the process was monitored and adjusted with a dilute H₂SO₄ solution to the optimal pH value of 3. Figure 4 shows that the initial concentration of 100 mg l⁻¹ indigo carmine dye was completely decolorized and degraded in only 1 and 2 minutes of electrolysis time at the applied current densities of 0.66 and 0.33 mA cm⁻² respectively. Compared to electrooxidation the electro-Fenton process is by far faster, due to the fast reaction of the indigo carmine dye and its molecule fragments with the very reactive OH⁻ radicals generated from corresponding reaction equation (Eq.4).

![Figure 4. Residual dye concentration versus time during the electro-Fenton treatment](image)

In addition to electro-Fenton degradation the indigo carmine dye or its molecule fragments can partially be absorbed and co-precipitate with the generated Fe(OH)₃ flocs and therefore be removed by electrocoagulation as pointed out in section 2.5.3. However, this way of dye removal by electrocoagulation is slow because of the low solution pH.

The electrical energy consumptions for dye degradation after 2 and 1 minutes of electrolysis time at the applied current densities of 0.33 and 0.66 mA cm⁻² are 4.75x10⁻³ and 5.23x10⁻³ kWh m⁻³ of treated dye solution respectively.

4. Conclusions

The electrooxidation process with Ti/Pt and graphite electrodes in the presence of NaCl as supporting electrolyte decolorizes indigo carmine dye due to indirect electrooxidation of the dye molecules in the bulk solution with the anodically generated chlorine. The electrical energy consumptions at the applied current density of 5 mA cm⁻² with Ti/Pt and graphite electrodes are 0.874 and 1.75 kWh m⁻³ of treated dye solution respectively.

The electrocoagulation process with iron electrodes is a more efficient method for decolorization of aqueous indigo carmine bearing solutions achieving 100% color removal in 35 and 20 minutes of electroprocessing at the applied current densities of 5 and 10 mA cm⁻² with the corresponding energy consumption 0.511 and 0.825 kWh m⁻³ of treated dye solution respectively. The electro-Fenton process with Fe electrodes and supplied H₂O₂ in acidic solution is the fastest and more efficient method for
degradation of indigo carmine dyes. Applying current densities of 0.33 and 0.66 mA cm\(^{-2}\) 100% the degradation of the dye was achieved in only 2 and 1 minutes of electroprocessing. The energy consumption was 4.75\(\times10^3\) and 5.23\(\times10^3\) kWh m\(^{-3}\) of treated dye solution.
