ABSTRACT

Denitrifying polyphosphate accumulating organisms (DNPAOs) are very promising for simultaneous nitrogen and phosphorus removal. While during denitrification, emission of a greenhouse gas, nitrous oxide (N\textsubscript{2}O), may occur. In this study, DNPAOs were enriched in a lab-scale reactor, and N\textsubscript{2}O emission was examined under different electron acceptor conditions. During the anoxic phase, with the uptake of phosphorus, denitrification of nitrate nitrogen (N\textsubscript{O3}-N) was observed without the accumulation of nitrite nitrogen (N\textsubscript{O2}-N). In general, a very low amount of N\textsubscript{2}O was produced with nitrate as the electron acceptor, independent of the applied different nitrate concentrations. However, with nitrite as the electron acceptor, a much higher N\textsubscript{2}O emission occurred. The N\textsubscript{2}O emission factor to the denitrified N\textsubscript{O3}-N was 6.2%, 5.3% and 4.9% at the initial N\textsubscript{O2}-N concentration of 10, 20 and 40 mg l\textsuperscript{-1}, respectively. In addition, a much higher N\textsubscript{2}O emission occurred with the co-existence of N\textsubscript{O3}-N and N\textsubscript{O2}-N. The initial organic carbon concentration had no significant effect on N\textsubscript{2}O emission with N\textsubscript{O3}-N as the electron acceptor. When stored organic carbon by DNPAOs was used as the electron donor, N\textsubscript{2}O emission was mainly dependent on the electron acceptor.

Keywords: nitrous oxide, denitrifying polyphosphate accumulating organisms, nitrite, intracellular stored organic carbon

1. Introduction

Denitrifying phosphate removal processes are very promising for simultaneous nitrogen and phosphorus removal, especially for treating organic carbon limited wastewater. It possesses characteristics of both denitrification and enhanced biological phosphorus removal. While during denitrification, emission of a greenhouse gas, nitrous oxide (N\textsubscript{2}O), may occur under certain conditions, such as high nitrite concentrations, low organic carbon to nitrogen ratios and low dissolved oxygen concentrations. N\textsubscript{2}O has a very high greenhouse effect potential, i.e., 300 times that of carbon dioxide (IPCC, 2001). Therefore, a small amount of N\textsubscript{2}O emission may cause a significant greenhouse effect. In addition, N\textsubscript{2}O is also an ozone depleting substance and should be carefully controlled. From the view of sustainable development, avoidance of secondary pollutants during wastewater treatment should be carried out. Therefore, it is necessary to examine N\textsubscript{2}O emission characteristics during biological nitrogen removal or during simultaneous biological nitrogen and phosphorus removal.

During denitrifying phosphate removal, microbial communities such as denitrifying polyphosphate accumulating organisms (DNPAOs), carry out denitrification using intracellular stored organic carbon (such as polyhydroxybutyrate, PHB) as the electron donor and nitrate or nitrite as the electron acceptor.

Tang B., Wu G., Wang H. and Guan Y. (2016), nitrous oxide emission depending on the type of electron acceptor by a denitrifying phosphorus removal sludge, Global NEST Journal, 18(X), XX-XX.
There are contrary results about the effect of intracellular organic carbon on the \( \text{N}_2\text{O} \) emission and the mechanism is still unclear (Kampschreur et al., 2009). Zeng et al. (2003) and Lemaire et al. (2006) found that a high \( \text{N}_2\text{O} \) emission (for example half of denitrified nitrate was converted to \( \text{N}_2\text{O} \)) occurred in anaerobic and aerobic processes, especially with activities of glycogen accumulating organisms (GAOs). The reason could be due to that the utilization rate of PHB was slow, which might cause a carbon limitation condition and induce a high \( \text{N}_2\text{O} \) emission (Meyer et al., 2005; Wang et al., 2011b; Zhou et al., 2013). In addition, during denitrification, a high accumulation of nitrite may also induce \( \text{N}_2\text{O} \) emission, especially when denitrifying activities were inhibited (Li et al., 2013b; Zhou et al., 2008; Wang et al., 2011a). Wu et al. (2013) obtained that when PHB was used as the organic carbon for denitrification, a high \( \text{N}_2\text{O} \) emission occurred when nitrite was coexisted. When the intracellular organic carbon is used for denitrification, whether the intracellular organic carbon itself or the existence of nitrite contributed to \( \text{N}_2\text{O} \) emission has not been clearly clarified (Kampschreur et al., 2009). Therefore, it is necessary to examine effect of different electron acceptors on \( \text{N}_2\text{O} \) emission during denitrification.

In this study, DNPAOs were enriched in a lab-scale reactor, and then characteristics of \( \text{N}_2\text{O} \) emission during denitrifying phosphorus removal was examined under different electron acceptor conditions.

2. Materials and methods

2.1. Denitrifying phosphate removal process

A sequencing batch reactor (SBR) with a working volume of 6 litres was operated at 25°C. The SBR had three cycles per day and each cycle comprised the following phases: fill (10 min), anaerobic (110 min), anoxic (180 min), aerobic (120 min), settle (40 min) and draw/idle (20 min). In each cycle, 3 litres of treated wastewater were exchanged with a new batch of synthetic wastewater. The reactor was constantly stirred with a mixer during the fill, anaerobic and aerobic phases. During the aerobic phase, air was supplied with an air diffuser located at the bottom of the reactor. During the anoxic phase, nitrate stock solution was dosed to achieve the initial nitrate nitrogen (\( \text{NO}_3\text{-N} \)) concentration of 30 mg l\(^{-1}\). Once a day, 400 ml of mixed liquor was withdrawn from the reactor just before the end of the aerobic phase, resulting in a solids retention time (SRT) of around 15 days if no solids loss occurred during the settling phase.

The components of the synthetic wastewater contained sodium acetate, yeast extract, \( \text{NH}_4\text{Cl} \), \( \text{Na}_2\text{HPO}_4 \), \( \text{MgSO}_4\cdot7\text{H}_2\text{O} \), \( \text{CaCl}_2\cdot6\text{H}_2\text{O} \) and trace elements. The influent chemical oxygen demand (COD) was around 400 mg l\(^{-1}\), ammonium nitrogen (\( \text{NH}_4\text{-N} \)) of 15 mg l\(^{-1}\) and orthophosphate (\( \text{PO}_4\text{-P} \)) of 15 mg l\(^{-1}\). The reactor was seeded with activated sludge taken from a Wastewater Treatment Plant in Shenzhen, China.

2.2. Batch denitrification experiments

Batch experiments with replications were carried out to examine effects of electron acceptors, initial nitrite nitrogen (\( \text{NO}_2\text{-N} \)) concentrations and initial PHB concentrations on \( \text{N}_2\text{O} \) emission. Average result data from replications were presented. The batch reactors were made from 500 ml capped glass flasks, each with three ports on the cap, one for liquid sampling, one for gas sampling, and the other for gas balance.

For the effect of electron acceptors, activated sludge mixed liquor was withdrawn from the SBR at the end of the anaerobic phase, and then different concentrations (\( \text{NO}_2\text{-N} \) of 15, 30 and 60 mg l\(^{-1}\), \( \text{NO}_3\text{-N} \) of 10, 20 and 40 mg l\(^{-1}\), and \( \text{NO}_3\text{-N/NO}_2\text{-N} \) of 30/5, 30/10, 30/20 mg l\(^{-1}\), respectively) of electron acceptors were added for commencing the experiment. For examining the effect of PHB on \( \text{N}_2\text{O} \) emission, the activated sludge was taken from the SBR at the end of the aerobic phase, and then different concentrations of COD (50, 100 and 200 mg l\(^{-1}\)) was added for accumulating PHB under anaerobic conditions. After that, \( \text{NO}_3\text{-N} \) of 30 mg l\(^{-1}\) was added to initiate the experiment. In all batch experiments, samples (both liquid and gas samples) were taken at intervals to test \( \text{NO}_2\text{-N} \) and \( \text{NO}_3\text{-N} \) for liquid samples, and \( \text{N}_2\text{O} \) for gas samples.
2.3. Analytical methods

NO\textsubscript{2}-N, NO\textsubscript{3}-N, suspended solids (SS), volatile suspended solids (VSS) and NH\textsubscript{4}-N were determined according to standard methods (APHA, 1995). The PHB concentration was detected by the modified HPLC method (Karr et al., 1983; Rodgers and Wu, 2010) with crotonic acid used for calibration. N\textsubscript{2}O was detected according to Wu et al. (2013).

3. Results and discussion

The system had been operated for more than 6 months and a very good DNPAOs activities had been obtained. The fraction of DNPAOs to PAOs was around 87% calculated from the aerobic and anoxic PO\textsubscript{4}-P uptake experiments (data not shown), showing that DNPAOs were successfully enriched inside the system. Dynamics of oxidized nitrogen and phosphorus are shown in Figure 1. During the anaerobic phase, a high amount of PO\textsubscript{4}-P was released, during the anoxic phase, PO\textsubscript{4}-P was taken up, and during the aerobic phase, PO\textsubscript{4}-P was further taken up. During the anoxic phase, with the uptake of PO\textsubscript{4}-P, denitrification of nitrate was observed without the accumulation of nitrite. In the study of Oehmen et al. (2010), similar phenomenon was also reported but was not emphasized. However, the phenomenon was different from other previous studies in DNPAO systems, where during the anoxic phase, denitrification of nitrate was accompanied with the nitrite accumulation (such as Li et al., 2013b and Wang et al., 2011a).

![Figure 1](image_url)

**Figure 1.** Dynamics of parameters within a typical SBR cycle.

Batch denitrification of nitrate or nitrite for DNPAOs under different oxidized nitrogen (NOx-N) concentrations are shown in Figure 2. In general, a very low amount of N\textsubscript{2}O was produced with NO\textsubscript{3}-N as the electron acceptor, with the N\textsubscript{2}O emission factor to the denitrified NO\textsubscript{3}-N of below 0.12%. However, with NO\textsubscript{2}-N as the electron acceptor, a much higher N\textsubscript{2}O emission occurred. At the initial NO\textsubscript{2}-N concentration of 10 mg l\textsuperscript{-1}, N\textsubscript{2}O emission occurred during the initial 30 min of the batch experiment, and then decreased with the complete consumption of NO\textsubscript{2}-N. While under the initial NO\textsubscript{2}-N concentration of 20 and 40 mg l\textsuperscript{-1}, N\textsubscript{2}O emission occurred during the whole batch experiment period. The N\textsubscript{2}O emission factor to the denitrified NO\textsubscript{2}-N was 6.2%, 5.3% and 4.9% at the initial NO\textsubscript{2}-N concentration of 10, 20 and 40 mg l\textsuperscript{-1}, respectively. In addition, the NO\textsubscript{2}-N reduction rate decreased with increasing NO\textsubscript{2}-N concentrations, with values of 11.1, 8.7 and 7.7 mg g VSS\textsuperscript{-1} h\textsuperscript{-1} at the NO\textsubscript{2}-N concentrations of 10, 20 and 40 mg l\textsuperscript{-1}, respectively.
Batch denitrification of DNPAOs under different NO\textsubscript{2}-N concentrations with the co-existence of NO\textsubscript{3}-N are shown in Figure 3. Similar to the effect of NO\textsubscript{2}-N alone, a high N\textsubscript{2}O emission was observed. The N\textsubscript{2}O emission factor to the denitrified NO\textsubscript{3}-N was 7.9%, 8.0% and 10.8% at the initial NO\textsubscript{2}-N concentration of 5, 10 and 20 mg l\textsuperscript{-1} with the co-existence of 30 mg l\textsuperscript{-1} NO\textsubscript{3}-N, respectively. The NO\textsubscript{3}-N reduction rate was 4.6, 5.6 and 6.4 mg g VSS\textsuperscript{-1} h\textsuperscript{-1} at the initial NO\textsubscript{2}-N concentration of 5, 10 and 20 mg l\textsuperscript{-1}, while the NO\textsubscript{x}-N reduction rate was around 6.0 mg g VSS\textsuperscript{-1} h\textsuperscript{-1} under all conditions. For NO\textsubscript{2}-N, it was reduced under the initial NO\textsubscript{2}-N concentration of 5 and 10 mg l\textsuperscript{-1}, while was produced at the initial NO\textsubscript{2}-N concentration of 20 mg l\textsuperscript{-1}.

Batch denitrification of DNPAOs under different initial PHB concentrations with NO\textsubscript{3}-N as the electron acceptor are shown in Figure 4. Similar to the effect of NO\textsubscript{3}-N alone, there was not much N\textsubscript{2}O emission, with the N\textsubscript{2}O emission factor to the denitrified NO\textsubscript{3}-N also below 0.12% under all conditions. This result indicated that the carbon to nitrogen ratio had no significant effect on N\textsubscript{2}O emission for the enriched DNPAOs when NO\textsubscript{3}-N was used as the electron acceptor.
Figure 3. N₂O emission under different NO₃⁻-N concentrations with the co-existence of nitrate

Figure 4. N₂O emission under different initial organic carbon concentrations
This study indicated that at least two types of metabolic modes were presented for DNPAOs. One was denitrifying nitrate with the accumulation of nitrite and the other was without the accumulation of nitrite. Special attention should be given when examination of DNPAO systems. For GAOs dominated denitrifying systems, there are also existing similar denitrifying modes. In the study of Lemaire et al. (2006), under batch experiments with nitrate or nitrite as the electron acceptor, N₂O emission occurred under both conditions even when nitrate was used as the electron acceptor and no NO₂⁻ accumulation, with the N₂O emission factor of 77% for nitrite and 26% for nitrate as the electron acceptor, respectively. Therefore, for PAOs or GAOs, the microbial community was an important factor inducing N₂O emission even with no NO₂⁻ accumulation. In addition, the high N₂O emission might also due to low diversity of denitrifiers (Lemaire et al., 2006).

When PHB was used as the electron donor, N₂O emission was dependent on the electron acceptor. When nitrate was used, there was not much N₂O emission, while when nitrite was used, a high N₂O emission occurred. Therefore, PHB was not the intrinsic reason causing N₂O emission during denitrification. In addition, the carbon to nitrogen ratios also had no significant effect on N₂O emission with nitrate as the electron acceptor. Wang et al. (2011b) showed that polyhydroxyalkanoate (PHA) degradation regulated the denitrifying phosphorus removal and N₂O production, and shorten anaerobic reaction duration from 90 min to 60 min could reduce the N₂O emission; in this system, denitrifying nitrate was accompanied with nitrite accumulation; N₂O emission decreased with increasing the PHA concentration. Zhou et al. (2013) compared DNPAOs denitrification utilizing intracellular organic carbon and external organic carbon, the N₂O emission was high at low carbon to nitrogen ratios with external organic carbons, and there was no much difference at high carbon to nitrogen ratios; in addition, PHA consumption was shown to be the limiting step for N₂O reduction, however, in this study, only the effect of NO₂⁻ was examined. Meyer et al. (2005) obtained that N₂O was a product of denitrification with stored PHA as the organic carbon.

As to the effect of nitrite, there are several opinions. The first reason could be due to that the accumulated NO₂⁻ induced a high N₂O emission. During denitrification, acetate could induce a high accumulation of NO₂⁻ and durther a high emission of N₂O, with the proportion of N₂O production to the applied influent nitrate of 74% (Adouani et al., 2010). Wang et al. (2011a) obtained that nitrite accumulation was up to 20 mg l⁻¹ during denitrifying phosphorus removal and the N₂O emission factor to the removed NO₂⁻ was 7.77%, while when the organic carbon was switched to propionate or acetate/propionate, the N₂O emission factor increased by 0.77 and 1.72 times. The second reason could be due to that the inhibition induced by NO₂⁻ or free nitrous acid (FNA). Zhou et al. (2008) obtained that the degree of inhibition of nitrite on DNPAOs was observed to be correlated much strongly with the FNA concentration than with the nitrite concentration, suggesting that FNA, rather than nitrite, was likely to be the true inhibitor on N₂O reduction. Fifty percent inhibition was observed at an FNA concentration of 0.0007-0.001 mg HNO₂⁻ N l⁻¹ (equivalent to approximately 3-4 mg NO₂⁻ N l⁻¹ at pH 7), while complete inhibition occurred when the FNA concentration was greater than 0.004 mg HNO₂⁻ N l⁻¹. The results also suggest that the inhibition on N₂O reduction was not due to the electron competition between N₂O and NO₂⁻ reductases. The inhibition was found to be reversible, with the rate of recovery independent of the duration of the inhibition, but dependent on the concentration of FNA the biomass was exposed to during the inhibition period. A higher FNA concentration caused slower recovery. The last reason could be due to the competition among the denitrifying reductases. Li et al. (2013b) obtained that N₂O generation accounted for 0.41% of the total nitrogen removal in denitrifying phosphorus removal process and the weak competition of N₂O reductase for electrons and the high nitrite accumulation were the two main reasons causing N₂O generation. The same group also obtained that N₂O emission increased with increasing the organic carbon concentrations, which could be due to that a high concentration of organic carbon induced a high production of PHA and consequently a high concentration of accumulated nitrite (Li et al. 2013a).

Therefore, due to the diversity of DNPAOs, different metabolism modes may be existed under different conditions. When examining N₂O emission in DNPAOs systems, effect of intracellular organic carbon,
nitrite and also organic carbon to nitrogen ratios, should be carefully analyzed with the consideration of acclimated DNPAOs.

4. Conclusions

DNPAOs were enriched in a lab-scale reactor, and a new phenomenon was examined. When stored organic carbon of DNPAOs was used as the electron donor, N\textsubscript{2}O emission was depended on the electron acceptor. When nitrate was used, there was not much N\textsubscript{2}O emission, while when nitrite was used, a high N\textsubscript{2}O emission potential occurred. In addition, when nitrate and nitrite existed simultaneously, N\textsubscript{2}O emission was higher than that when only nitrite existed. Therefore, PHA was not the intrinsic reason causing N\textsubscript{2}O emission during denitrification for the acclimated DNPAOs and the electron acceptor played an important role in N\textsubscript{2}O emission.
