Abstract

In the present work, the degradation of phenol from aqueous solutions was investigated using periodate/zero valent iron nanoparticle (nZVI) in the presence of ultrasound at a batch reactor. The Experimental tests were carried out using pre-designated concentrations of nZVI, periodate, and pH ranging from 1-7 mM, 0.5-5 mM, 3-11 respectively. During the all experimental tests the ultrasonic reactor was operated at a fix frequency (40 kHz), temperature (33±1) and power (350 W). The results of nZVI/periodate/ultrasound system on degradation of phenol showed that the removal efficiency was indeed affected by the amount of free radicals produced to initiate the oxidative decomposition of phenol. also, by increasing the nZVI loading to 3 mM and periodate concentration to 3 mM, the efficiency of phenol removal was increased. Besides, the acidic pH (pH = 3) was found to be more effective than neutral and alkaline pH in degradation of phenol.

Keywords: Periodate, nZVI, ultrasound, phenol, degradation.

1. Introduction

Wastewater caused by industrial activities might be contained by various chemical compounds in the quantities that can change the quality of water resources. Many of these compounds are organic-based, toxic, and characterized by high stability in the environment (Rahmani et al., 2016). The presence of recalcitrant organic compounds in the environment is undesirable and will create various unpleasant unfavorable consequences for all creatures (Baziar et al., 2018a). Phenol (C₆H₅OH), a well-known toxic and hazardous organic compound, has been widely utilized in several industries like pulp and paper, paint, petrochemical, herbicide and pesticide production (Azevedo et al., 2006; Manshouri et al., 2012; Ghasemi et al., 2015). The wastewater generated from these industries might be introduced to the surface and groundwater. As a result, it can produce severe adverse effects on aquatic life as well as human health with exacerbating the water contamination issues (Zhong et al., 2011). Phenol has been listed by USEPA as a priority pollutant due to high perniciousness on human and biota, high permanence in the aquatic environment, low biological decomposition property, high carcinogenic and mutagenic nature (Azevedo et al., 2006). Consequently, the elimination of this compound and its derivatives from industrial effluent/wastewater is an environmental concern.

A number of treatment methods to eliminate the phenol from contaminated water and/or from industrial wastewater (e.g., treatment by biological, physico-chemical and advanced oxidation process approaches) have been extensively investigated. From above mentioned procedures, the application of biological treatment compared to the other two methods has recently fallen out of favor due to the toxicity of phenol to the bacteria (the organism that is responsible for decomposition) as well as its low efficacy and long time needed for adaptation of the bacteria water contaminated with phenol. Physico-chemical techniques are usually needed after treatment or disposal of produced sludge (Alavi et al., 2018; Baziar et al., 2018b). In the last few decades, applications of AOPs in the aqueous solution have been increasingly used because of their good performance to degrade a broad range of persistent organic pollutants (Seidmohammadi et al., 2016; Seid-Mohammadi et al., 2015; Seidmohammadi et al., 2018; Naghan et al., 2015). The performance of AOPs are underlying the production of strong reactive intermediates, e.g. sulfate (SO₄²⁻), hydroxyl (OH⁻) and iodyl (IO₃⁻) via different activation methods. Therefore, these

strong intermediates can entirely degrade the persistent organic pollutants to CO₂ and H₂O or convert them to a less toxic product (Lee et al., 2014).

More recently, the application of periodate (IO₄⁻) as an oxy-anion in water treatment has attracted increasing attention (Saïen et al., 2018). The interest underlying the periodate usage in decomposition of persistent organic pollutants are associated with its(I) relatively high oxidation potential (EO = 1.6 V), (II) high dissolution capacity in water, (III) stability at room temperature and (IV) generation of free radicals (e.g. IO₃⁻, IO₂⁻) through reactions of intermolecular electron transfer (Lee et al., 2014). Although the oxidation potential of periodate anion is acceptable however, its oxidation reactions are relatively slow at a room temperature and also serve selectively to oxidize the organic compounds. The previous studies confirmed that periodate can be activated by ultraviolet (UV) irradiation as illustrated by equations of 1 to 3 and produce free radicals of IO⁻ and OH• which can degrade organic matters (e.g., 4-chlorophenol and dye), (see Equations 1 to 3) (Chia et al., 2004; Lee et al., 2004).

\[
\text{IO}_4^- + h\nu \rightarrow \text{IO}_3^- + \text{O}_2
\]  
(1)

\[
\text{O}_2^- + \text{H}^+ \rightarrow \text{OH}^-
\]  
(2)

\[
\text{IO}_3^- + 4-\text{CP} \rightarrow \text{IO}_3^- + \text{oxidized products}
\]  
(3)

A great substitution to UV irradiation is ultrasonic (US) radiation. US radiation influence on molecules is related to nucleation, cavitations along with formation of micro-bubbles. The micro-bubbles produced provide areas of high pressure in the system which can generate OH• radicals through dissociation of water. Therefore ultrasonic radiation is mainly used in numerous technologies for water purification (Dobaradaran et al., 2018; Zhou et al., 2015; Ammar, 2016). The generated OH• radicals can non-selectively degrade the organic compounds, therefore they reduce the selective nature of periodate in degradation of organic compounds. Also, the main advantage of this method is high ability to degrade hazardous material to non-hazardous end products (Lee et al., 2014; Harrabi et al., 2018). The combination of ultrasonic waves with oxidants like IO₄⁻ can accelerate the removal of organic components from aqueous solutions (Seid-Mohammadi et al., 2015).

Moreover, it has been proven that addition of Nano zero valent iron (nZVI) along with an oxidant (e.g., persulfate, hydrogen peroxide, etc.) in aqueous solutions can enhance the elimination of organic compounds by increasing the generation of powerful free radicals such as OH• and SO₄²⁻ (Harrabi et al., 2018; Zhou et al., 2008). The most important feature of nZVI is its high surface area which can accelerate the production of oxidants (Baziar et al., 2018b). However, it is reported that the formation of iron oxide layers (passive layers) on the surface of nZVI may dramatically reduce the reactivity of nZVI and retard the generation free radicals (Song et al., 2019). Hence, in the present work we evaluate the role of US radiation as a destructive agent of iron passive layer, as well as nZVI loading and periodate dosage as factors that can improve the performance of US/nZVI/IO₄⁻ system for degradation of phenol.

2. Materials and methods

2.1. Chemicals

The chemicals used in this study are as follows: phenol (99.8%; Merck Co.), Sodium periodate (99%; Sigma-Aldrich), potassium ferricyanide (99%; Merck Co.), 4-aminoantipyrine (98%; Merck Co.), Nanoparticle Zero Valent Iron powder (97%; particle size 30-60 nm; Merck Co.), KH₂PO₄ (>99%, Sigma-Aldrich ), K₂HPO₄ (>98%; Sigma-Aldrich ), NH₄OH (Merck Co.), H₂SO₄ and NaOH (Merck Co.).

2.2. Experimental procedure

All experimental tests were performed in an ultrasonic stainless steel reactor (LUC-model 405) with dimensions of 15 cm × 13 cm × 25 cm and with a total volume of 5 L. Figure 1 shows the schematic diagram of used ultrasonic reactor which was operated at a fixed frequency (40 kHz), temperature (33±1) and power (350 W) during the all experimental tests. The ultrasonic reactor used in this study consists of three parts: (i) turbulent regime tank, (ii) ultrasonic generator, (iii) transformer.

![Figure 1. The schematic diagram of the ultrasonic reactor](image)

To study the phenol degradation, the nZVI and sodium periodate with pre-designated concentrations (nZVI 0.5-5 mM and sodium periodate 1-7 mM) were mixed with an appropriate concentration of phenol (25-200 mg/L) in a beaker with a final volume of 100 mL. Then the solution pH (3-11) was adjusted with H₂SO₄ and NaOH (0.1 mol/L). The final solution was transferred to the ultrasonic stainless steel reactor (to get exposure with ultrasound waves) and stirred by a magnetic stirrer to obtain a homogenous solution within the process reaction times of 0-120 min. The initial and final concentration of phenol in samples was measured using UV-visible spectrophotometer at a wavelength of 500 nm (Deng et al., 2014). The removal efficiency of the developed system in various operation conditions was determined by Equation (4).
Here, $C_i$ and $C_f$ are related to the initial and final concentration of phenol in the developed system, consecutively. It is noted that, prior to phenol measurement in the samples, they were centrifuged for 5 min at a rotational speed of 1000 rpm to remove the final Fe$^{2+}$.

3. Results and discussion

3.1. Effect of pH in Us/IO$_4^-$/Fe$^*$ system

The effect of pH on phenol degradation in the Us/IO$_4^-$/Fe$^*$ system was studied by changing its level between 3 and 11. It is quite obvious that in AOPs reactions the presence of several oxidants in the process increases the power of degradation. It is clear that the pH values ranging between acidic and neutral. The first is bringing the reaction pathway for free radicals and second is bringing in the 1 electron transfer in a neutral condition by adjusting the initial solution pH in the process. However, the latter is not completely understood and there has not been an explanation for it recently (Lee et al., 2014).

In addition, in an acidic pH, Fe$^*$ can enhance the degradation of phenol in the presence of dissolved O$_2$ with a mechanism of 2-electron transfer and formation of hydrogen peroxide. The generated hydrogen peroxide can also reduce to H$_2$O with a new reaction of 2-electron transfer. Next, the interaction between the hydrogen peroxide and ferrous iron (Fe$^{2+}$) can form OH$^-$ radicals (see Equations 11 to 13) (Hussain et al., 2014).

\[
\begin{align*}
\text{Fe}^* + \text{O}_2 + 2\text{H}^- & \rightarrow \text{Fe}^{2+} + \text{H}_2\text{O}_2 \\
\text{Fe}^* + \text{H}_2\text{O}_2 + 2\text{H}^- & \rightarrow \text{Fe}^{2+} + 2\text{H}_2\text{O} \\
\text{Fe}^{2+} + \text{H}_2\text{O}_2 & \rightarrow \text{Fe}^{3+} + \text{OH}^- + \text{OH}^-
\end{align*}
\]

Generally, two reaction pathways are assumed for free radical generation at the pH values ranging between acidic and neutral. The first is bringing the H$^+$ in an acidic condition and second is bringing in the 1 electron transfer in a neutral condition by adjusting the initial solution pH in the process. However, the latter is not completely understood and there has not been an explanation for it recently (Lee et al., 2014).

\[
\begin{align*}
\text{Fe}^* + \text{O}_2 + 2\text{H}^- & \rightarrow \text{Fe}^{2+} + \text{H}_2\text{O}_2 \\
\text{Fe}^* + \text{H}_2\text{O}_2 + 2\text{H}^- & \rightarrow \text{Fe}^{2+} + 2\text{H}_2\text{O} \\
\text{Fe}^{2+} + \text{H}_2\text{O}_2 & \rightarrow \text{Fe}^{3+} + \text{OH}^- + \text{OH}^-
\end{align*}
\]

3.2. Effect of periodate concentration on the Us/IO$_4^-$/Fe$^*$ system

The effect of periodate concentration on the performance of Us/IO$_4^-$/Fe$^*$ system was investigated by adjusting the concentration from 1 mM to 7 mM and keeping Fe$^*$ concentration at 2 mM with a reaction time ranging between 0-60 min. As illustrated in Figure 3, by increasing the periodate concentration from 1 mM to 2 mM, the phenol removal efficiency increased from 86.2% to 93.6%. However, further increasing the periodate concentration had negative influence on the system performance and the removal efficiency decreased. It is clear that the periodate concentration and its activation process play important roles in the enrichment of periodate reactive species (like IO$_4^-$ and IO$_3^-$) and the corresponding removal efficiency. When an adequate amount of periodate is fed...
to the system, in the presence of an activator, the removal efficiency increases. This trend can be explained by the production of free radicals in large enough amounts to degrade the organic compound. Although higher periodate concentrations (more than 2 mM) produce higher amounts of radicals, the generated radicals can react with each other or with IO₄⁻ in a radical destructive reaction. Therefore, these reactions can reduce overall removal efficiency. Equation (14) presents an example of scavenging reaction which can occur in the Us/IO₄⁻/Fe⁺ system at an excess level of periodate concentration (Temiz et al., 2016).

\[
\text{OH}^+ + \text{IO}_4^- \rightarrow \text{OH}^- + \text{IO}_4^-
\]  

(14)

As mentioned above, Fe⁺ can decompose an organic pollutant through transfer of two electrons to the dissolved oxygen to generate hydrogen peroxide (Equation 11). The hydrogen peroxide formed can be converted to H₂O with another transfer of two electrons from Fe⁺ (Equation 12). The products of reactions (H₂O₂ and Fe²⁺) can be combined together to produce the Hydroxyl free radicals. However, with excessive loading (concentration) of Fe⁺, a large amount of Fe²⁺ is produced. It can scavenge hydroxyl free radical via following reaction (Tang et al., 2008):

\[
\text{Fe}^{2+} + \text{OH}^- \rightarrow \text{Fe}^{3+} + \text{OH}^-
\]  

Therefore, the obtained results propose that, if the dosages of Fe⁺ and periodate exceed the optimal value, the removal efficiency decreases subsequently. This work demonstrated that the addition of sufficient dosages of the Fe⁺ and periodate were greatly important in decomposing phenol in water solutions.

### 3.3. Effect of NZVI concentration on the Us/IO₄⁻/Fe⁺ system

Figure 4 presents the phenol degradation under various Fe⁺ concentrations in the Us/IO₄⁻/Fe⁺ system. As seen, the phenol degradation was extensively impacted by Fe⁺ loading and the phenol degradation percentage improved from 0% to 96.6% when Fe⁺ concentration increased from 0 to 3 mM in the system. This pattern can be explained by: (i) an increase in the total surface area with increasing the Fe⁺ loading, which creates a contribution to the increase in the iron corrosion, (ii) an increase in the corrosion products (like Fe⁷⁺, Fe⁵⁺, etc.) by increasing the Fe⁺ loading in an acidic medium that can produce free radicals to decompose the phenol (Baziar et al., 2018a). However, further increasing the Fe⁺ loading (more than 3 mM) led to the reduction of system performance and, as a result, the removal percentage of phenol decreased.

In the next step of work, we compared the performance of Us/IO₄⁻/Fe⁺ system with US/IO₄⁻ and IO₄⁻/Fe⁺, and also with IO₄⁻ and US alone. In fact, the purpose of this stage of the study was to identify the function of each variable used in the system of Us/IO₄⁻/Fe⁺ for phenol degradation.
DEGRADATION OF PHENOL USING US/PERIODATE/NZVI SYSTEM FROM AQUEOUS SOLUTIONS

3.5. Effect of CaCl₂ on the degradation of phenol in US/IO₄⁻/Fe⁺ system

In the natural water environments, the activation of IO₄⁻ may be affected due to the presence of background ions. Hence, we investigated the influence of CaCl₂, a compound or salt that can easily dissolve in aqueous solutions and generate ions of calcium and chloride. Three individual tests were performed to determine the effect of CaCl₂ on the performance of US/IO₄⁻/Fe⁺ system by adjusting the CaCl₂ concentration in the values of 0.13, 0.5, and 1.03 g/L. As presented in Figure 7, the selected concentrations posed a little effect to the decomposition of phenol.

3.6. COD removal in US/IO₄⁻/Fe⁺ system

One of the most well-known methods for determination of persistent organic matter degradation in wastewater treatment is chemical oxygen demand (COD) [Baziar et al., 2018c]. Determination of COD in our work is highly important, because of its potential to oxidize the organic pollutants like phenol using dichromate. In fact, the degree of oxidation of the process is determined by the extent of reduced COD. This test was conducted to find out the effectiveness of the process in degradation of phenol at the optimum values of parameters as determined in the previous steps. Figure 8 illustrates the performance of US/IO₄⁻/Fe⁺ on reduction of COD in a treatment test with three replications. As seen in this figure the performance of the developed system is about 85% in average. Therefore, it can be concluded that the process has high efficiency in eliminating COD. It is noted that for comparison we performed two separate tests using US/IO₄⁻ and IO₄⁻/Fe⁺ processes in the same conditions. The results showed that US/IO₄⁻ and IO₄⁻/Fe⁺ can remove COD up to 38% and 29% on average, respectively.

Figure 6. Effect of NZVI on periodate activation in the absence of ultrasonic waves on the phenol degradation. pH 3, periodate 2 mM, NZVI 3 mM, phenol concentration 50 mg/l, duration 60 min

Figure 7. The impact of ion intensity on the decay of phenol in the Us/IO₄⁻/Fe⁺ system. pH = 3, periodate 2 mM, NZVI 3 mM, phenol concentration 50 mg/l, duration 60 min

Figure 8. The impact of Us/IO₄⁻/Fe⁺ systems (combined and isolated) for COD removal. pH = 3, periodate 2 mM, NZVI 3 mM, phenol concentration 50 mg/l, duration 60 min
3.7. Proportion of OH radicals on degradation of phenol in the US/nZVI/periodate process

In this study, tert-butyl alcohol (TBA) with a concentration of 1 M was used to quench OH radicals in the US/nZVI/periodate process with the aim of identifying the contribution of OH radical on degradation of phenol. In the previous studies, it has been demonstrated that TBA with no alpha hydrogen can completely destroy the hydroxyl radicals in aqueous solutions (Baziar et al., 2018b). It is marked from the laboratory radical scavenger test that the addition of TBA extensively decreased the decomposition of phenol. As already mentioned, the degradation of phenol in the optimized conditions of the process was 96.6% (without using radical scavenger). The addition of TBA, however, decreased the phenol decomposition to 43.2%. Therefore, it can be concluded that the contribution of hydroxyl radical to the degradation of phenol in optimal conditions is 56.4% and the share of other radicals (like IO2-, IO3-) is 43.2%.

3.8. Kinetic of phenol decomposition in the US/IO2-/Fe* system

In this experiment, the effects of different parameters such as periodate concentration, nZVI loading; pH and initial phenol concentration on the kinetic of phenol decomposition were studied using modified Langmuir–Hinshelwood model (Equation 17) (Dobaranadan et al., 2018). Table 1 shows the constant of first-order reaction rate (k-value) and the determination coefficient (R²-value) of each parameter used in the system. As observed in this table, the R²-values of all experimental tests were above 0.8. These results support the conclusion that phenol degradation in the process of US/Periodate/nZVI follows a first-order kinetic model. In addition, it can be concluded that the reaction rate (k) is significantly dependent on the concentration of phenol. For instance, at phenol concentration of 25 mg/L, the decomposition rate of phenol was 0.0827 min⁻¹, while the reaction rate at phenol concentration of 200 mg/L was decreased to 0.0039 min⁻¹.

\[
\ln \left( \frac{C}{C_0} \right) = -kt
\]

where k is the rate constant; C and C₀ are initial and final concentrations of phenol in the system.

4. Conclusion

The results of this study revealed that the US/Periodate/nZVI system is robust in degradation of phenol with an initial concentration of 50 mg/L by 5 mM nano zero valent iron, 3 mM periodate at an ultrasonic reactor with a fix frequency (40 kHz), temperature (33±1°C) and power (350 W) within 1 h. It is also established in the present work that phenol degradation by US/Periodate/nZVI system follows the first-order kinetics. In addition, the results of COD removal showed that US/Periodate/nZVI system is effective in elimination of COD from aqueous solutions. It can be concluded that the developed system is a promising and effective method for degradation of phenol from water solutions.
